(57) Ultrafast x-ray imaging detector.

(57) An X-ray detector including a photocathode arranged to receive X-ray radiation and being operative to provide in response thereto an output of electrons, and at least one electron multiplier operative at subatmospheric pressure and in response to the output of electrons from the photocathode to provide an avalanche including an increased number of electrons.

EP 0 450 571 A2

FIELD OF THE INVENTION

The present invention relates to detectors generally and more particularly to X-ray detectors.

BACKGROUND OF THE INVENTION

Various types of X-ray detectors are known, including varieties of gas-filled imaging detectors which are based on the conversion of X-ray photons in the gas volume to electrons and on the proportional amplification of the released photoelectrons in various wire electrode assemblies. Such detectors are described by J.E. Bateman in "Detectors for Condensed Matter Studies", Nuclear Instruments and Methods, A273 (1988) 721-730. Bateman also describes other X-ray photon detectors such as various solid scintillators and semiconductor devices.

There are also known gas scintillation detectors of various types as described by M.R. Sims, A. Peacock and B.G. Taylor, "The Gas Scintillation Proportional Counter", Nuclear Instruments and Methods, 221 (1984) 168-174. Various X-ray photon detectors are also described in U.W. Arndt, J. Appl. Cryst. 19 (1986) 145.

Gas-filled detectors are by far the most efficient and flexible X-ray detectors. They offer high localization resolution and good linearity, moderate-to-high counting rate capability, and a large variety of geometries over large active areas. However, gaseous (gas filled) detectors have the following disadvantages:

1. The X-ray to electron conversion in the gas causes a geometrical parallax error for photons impinging at an angular incidence.
2. The localization accuracy is limited, due to the relatively large range of photoelectron motion in the gas.
3. Space charge effects limit the counting rate.
4. The gas multiplication process in proportional detectors and the light production in gas scintillation detectors are relatively slow processes which limit the time resolution to between tens of nanoseconds and tens of microseconds.
5. A gas medium is not an efficient converter of energetic photons in the energy range of above about 10 KeV, even for high - Z Xenon gas.

Detectors having a relatively rapid response capable of operating at high X-ray flux are important in applications such as X-ray diffraction analysis in synchrotron radiation accelerators and X-ray radiography with intense X-ray generators. Fast detectors are also important when time correlated information is needed, as in the study of dynamic processes, as described in A.R. Faruqi, Nuclear Instruments and Methods, A273 (1988) 754.

Efficiency of X-ray detectors is exceedingly important, since any increase in efficiency enables X-ray dosages applied to subjects in therapeutic and diagnostic applications to be correspondingly reduced.

A state of the art X-ray detector for medical applications is described in Baru, S. E. et al. "Multiwire proportional chamber for a digital radiographic installation", Nuclear Instruments and Methods in Physics Research A283 (1989), pp. 431 -435, the disclosure of which is incorporated herein by reference.

An X-ray detector for high flux operation is described in "A Novel Unidimensional Position Sensitive Multiwire Detector" by J. Derion and M. Ruscey, IEEE Transactions on Nuclear Science, Vol. NS-34, No. 1, February 1987, pp. 442 - 448.

The inventors have published papers on imaging of photoelectrons using avalanche chambers including the following:

"High Accuracy Imaging of Single Photoelectrons by Low-Pressure Multistep Avalanche Chamber Coupled to a Solid Photocathode" by A. Breskin and R. Chechik, Nuclear Instruments and Methods in Physics Research 227,(1984) 24-28.

SUMMARY OF THE INVENTION

The present invention seeks to provide an improved X-ray detector, which is characterized by high detection efficiency and speed, the capability to operate at high X-ray fluxes and to provide high two dimensional imaging accuracy.

There is thus provided in accordance with a preferred embodiment of the present invention an X-ray detector including a photocathode arranged to receive X-ray radiation and being operative to provide in response thereto an output of electrons, and at least one electron multiplier operative at subatmospheric pressure and in response to the output of electrons from the photocathode to provide an avalanche including an increased number of electrons.

According to another preferred embodiment of the invention the electron multiplier is operative at any suitable (not necessarily subatmospheric) pressure and the electron multiplier may be a multistage electron multiplier.

Preferably, there is also provided an electrode and a readout system for detecting the electrons produced by the electron multiplier, or alternatively, an optical recording system which records photons produced during the electron multiplication process.

In accordance with one embodiment of the invention, the photodetector includes one or more photocathode foils, which may be formed of CsI, CuI, Au, Ta etc. According to an alternative embodiment of the invention, the photodetector may include a porous or amorphous material such as CsI having typically 1% - 3% of the bulk density.

In accordance with one embodiment of the invention, the electron multiplier includes a large area, preferably relatively low-pressure multistage chamber, with various electrode geometries and readout methods. Alternatively, the chamber may be at any suitable pressure.

Further in accordance with a preferred embodiment of the present invention, the X-ray detector includes at least one detecting means for detecting an indication of at least one characteristic of the electron avalanche produced by the electron multiplier.

In accordance with an alternative preferred embodiment of the present invention, the at least one electron multiplier includes at least one detecting means for detecting an indication of at least one characteristic of the electron avalanche produced by the electron multiplier.

Further in accordance with a preferred embodiment of the present invention, the X-ray detector also includes a large area chamber and at least the photocathode and the at least one electron multiplier are located interiorly of the chamber. Still further in accordance with a preferred embodiment of the present invention, a non-aging high gain-providing gas is provided interiorly of the chamber.

Additionally in accordance with a preferred embodiment of the present invention, the electron multiplier defines at least one amplification stage and at least one transfer stage.

Further in accordance with a preferred embodiment of the present invention, the at least one amplification stage includes at least two amplification stages.

Still further in accordance with a preferred embodiment of the present invention, at least one of the at least one transfer stages is defined before the at least one amplification stage.

Additionally in accordance with a preferred embodiment of the present invention, the at least one transfer stage includes a plurality of transfer stages.

Still further in accordance with a preferred embodiment of the present invention, the plurality of transfer stages includes at least three transfer stages.

Additionally in accordance with a preferred embodiment of the present invention, at least one of the at least one transfer stages is defined after the amplification stage.

Still further in accordance with a preferred embodiment of the present invention, the electron multiplier

includes at least one gate electrode before at least one of the at least one amplification stages for receiving a selected one of at least two selectable voltage levels.

Further in accordance with a preferred embodiment of the present invention, the at least one gate electrode includes at least two gate electrodes.

5 Still further in accordance with a preferred embodiment of the present invention, the electron multiplier also defines a pre-amplification stage before the amplification stage.

Additionally in accordance with a preferred embodiment of the present invention, at least one of the at least one transfer stages is defined before the preamplification stage and the at least one amplification stage.

10 Further in accordance with a preferred embodiment of the present invention, the detecting means includes electron detection means for detecting the electrons produced by the electron avalanche.

Still further in accordance with a preferred embodiment of the present invention, the electron detection means includes a plurality of pad electrode assemblies for collecting the electrons produced by the electron multiplier.

15 Additionally in accordance with a preferred embodiment of the present invention, each of the pad electrode assemblies includes a pad electrode, an insulative layer and a resistive layer.

Still further in accordance with a preferred embodiment of the present invention, the electron detection means includes at least one strip electrode array, the strip electrode array including a first plurality of mutually parallel strip electrodes, generally planar insulating means, defining a plane generally parallel to
20 the first plurality of mutually parallel strip electrodes and a second plurality of mutually parallel strip electrodes, arranged generally parallel to the plane and generally perpendicular to the first plurality of strip electrodes.

Further in accordance with a preferred embodiment of the present invention, the detecting means includes photon detection means for detecting photons emitted during the electron avalanche.

25 Still further in accordance with a preferred embodiment of the present invention, the photocathode is generally planar and is configured and arranged to receive X-ray radiation impinging on both sides thereof.

Additionally in accordance with a preferred embodiment of the present invention, the at least one electron multiplier includes two electron multipliers.

Further in accordance with a preferred embodiment of the present invention, the at least one detecting
30 means includes two detecting means.

Still further in accordance with a preferred embodiment of the present invention, the at least one electron multiplier includes two electron multipliers disposed respectively on the two sides of the planar photocathode.

35 Additionally in accordance with a preferred embodiment of the present invention, the at least one detecting means includes two detection means disposed respectively on the two sides of the planar photocathode.

Further in accordance with a preferred embodiment of the present invention, the photocathode includes a metal foil.

40 Still further in accordance with a preferred embodiment of the present invention, the photocathode includes an insulative support layer and at least one semiconductive layers disposed on respective at least one sides of the support layer.

Additionally in accordance with a preferred embodiment of the present invention, the photocathode includes an insulative support layer and at least one conductive layers disposed on respective at least one
45 sides of the support layer.

Further in accordance with a preferred embodiment of the present invention, the photocathode includes a conductive support layer and at least one insulative layer disposed on respective at least one sides of the support layer.

50 Still further in accordance with a preferred embodiment of the present invention, the photocathode includes a conductive support layer and at least one semiconductive layer disposed on respective at least one sides of the support layer.

Additionally in accordance with a preferred embodiment of the present invention, the photocathode includes an insulative support layer and at least one noninsulative element disposed on respective at least one sides of the support layer, each noninsulative element including a semiconductive layer and a conductive layer.

55 Further in accordance with a preferred embodiment of the present invention, the photocathode includes an insulative support layer and at least one photocathode element disposed on respective at least one sides of the support layer, each photocathode element including an insulative layer and a conductive layer.

Still further in accordance with a preferred embodiment of the present invention, the photocathode

includes a conductive support layer and at least one low-temperature non-conductive layers disposed on respective at least one sides of the support layer.

Additionally in accordance with a preferred embodiment of the present invention, the photocathode includes a support layer and at least one photocathode element disposed on respective at least one sides of the support layer, each photocathode element including a metal layer and a nonconductive layer.

Further in accordance with a preferred embodiment of the present invention, the photocathode includes a porous material.

Still further in accordance with a preferred embodiment of the present invention, the at least one characteristic includes at least one of the following characteristics: the number of electrons in the avalanche, the location of the avalanche, and the time of occurrence of the avalanche.

Additionally in accordance with a preferred embodiment of the present invention, the gas is generally light-emitting.

Still further in accordance with a preferred embodiment of the present invention, the at least one detecting means includes at least one electrode for providing the avalanche and for providing the indication of the at least one characteristic of the electron avalanche.

Further in accordance with a preferred embodiment of the present invention, the at least one electrode includes a plurality of conductive elements.

Still further in accordance with a preferred embodiment of the present invention, the plurality of conductive elements includes a plurality of wires.

Further in accordance with a preferred embodiment of the present invention, there is provided an X-ray detector assembly including a gas filled enclosure and a plurality of X-ray detectors located interiorly of the gas filled enclosure, each individual one of the plurality of X-ray detectors preferably being constructed and operative as above.

In accordance with a further preferred embodiment of the present invention there is provided an X-ray detecting method including the steps of providing a photocathode arranged to receive X-ray radiation and being operative to provide in response thereto an output of electrons, and, in response to the output of electrons from the photocathode, providing at sub-atmospheric pressure an avalanche including an increased number of electrons.

Further in accordance with a preferred embodiment of the present invention, the method also includes the step of detecting an indication of at least one characteristic of the electron avalanche.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention will be understood and appreciated from the following detailed description, taken in conjunction with the drawings in which:

Fig. 1A is a schematic illustration of a X-ray photon detector having an electronic readout which is constructed and operative in accordance with one preferred embodiment of the present invention;

Fig. 1B is a schematic illustration of a X-ray photon detector constructed and operative in accordance with another preferred embodiment of the present invention;

Fig. 1C is a schematic illustration of a X-ray photon detector constructed and operative in accordance with yet another preferred embodiment of the present invention;

Fig. 1D is a schematic illustration of a X-ray photon detector constructed and operative in accordance with still another preferred embodiment of the present invention;

Fig. 1E is a schematic illustration of a X-ray photon detector constructed and operative in accordance with a further preferred embodiment of the present invention;

Fig. 1F is a schematic illustration of a X-ray photon detector constructed and operative in accordance with yet a further preferred embodiment of the present invention;

Fig. 1G is a schematic illustration of a X-ray photon detector constructed and operative in accordance with still a further preferred embodiment of the present invention;

Fig. 1H is a schematic illustration of a X-ray photon detector constructed and operative in accordance with an additional preferred embodiment of the present invention;

Fig. 1I is a schematic illustration of a X-ray photon detector constructed and operative in accordance with another preferred embodiment of the present invention;

Fig. 2A is a schematic illustration of an X-ray photon detector combined with an optical sensor which is constructed and operative in accordance with a preferred embodiment of the present invention;

Fig. 2B is a schematic illustration of an X-ray photon detector combined with an optical sensor which is constructed and operative in accordance with another preferred embodiment of the present invention;

Figs. 3A, 3B, 3C and 3D are planar illustrations of various embodiments of electrodes useful in the

apparatus of Figs. 1A - 2B;

Fig. 4A is a schematic illustration of an X-ray photon detector which is capable of detecting photons impinging on both sides of a planar photocathode;

Fig. 4B is a schematic illustration of an alternative embodiment of X-ray photon detector which is capable of detecting photons from both sides of a planar photocathode;

Fig. 5 is a schematic illustration of an X-ray photon detector assembly comprising a plurality of stacked X-ray photon detector modules;

Figs. 6A - 6G are sectional illustrations of seven alternative embodiments of photocathode assemblies useful in the present invention; and

Figs. 7A - 7B illustrate results of an experiment demonstrating the relative efficiencies of X-ray detection apparatus respectively including the photocathodes of Figs. 6A and 6C.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

Reference is now made to Fig. 1A, which illustrates an X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. The X-ray detector, indicated generally by reference numeral 10 comprises a preferably low-pressure gas filled enclosure 12 including a gas entry conduit 13, an X-ray photon entrance window 14, and a gas exit conduit 15. The circulated gas is typically at approximately 20 Torr pressure and at stabilized room temperature. Alternatively, the apparatus can operate at any other suitable pressure. The examples set forth hereinbelow are directed to subatmospheric pressure applications.

Entrance window 14 is typically formed of polypropylene or of Mylar or Kapton foil and is supported on a frame 16. The thickness of the foil may vary as a function of the energy of the impinging X-ray photons. For example, for photons of energy 10 KeV, a preferred thickness would be 5-10 microns.

X-ray photons passing through window 14, as indicated by reference numeral 18, impinge on a photocathode 20. Various embodiments of photocathodes suitable for use in the apparatus of Fig. 1A, are illustrated in Figs. 6A - 6G and are described in detail hereinbelow. The impingement of the X-ray photons on the photocathode 20 causes the release of electrons from the photocathode at the location of the impingement. The released electrons are amplified in a pre-amplification stage 22 to produce an initial avalanche, as illustrated by reference numeral 24. The electron avalanche is transferred via a transfer gap 26 to an amplification stage 28, which produces a second avalanche 30.

The electrons in second avalanche 30 are transferred through a second transfer stage 32 and are collected by an array 34 of pad electrodes 36. A typical configuration of array 34 of pad electrodes 36 is shown in Fig. 3C. The pad electrodes are typically of square configuration and of side length 2 - 10 mm. Preferably the pad electrodes 36 are separated from adjacent pad electrodes by 0.1 - 0.3 mm. The pad electrodes are preferably formed of copper formed over an epoxy laminated printed circuit board. The output signals of electrodes 36 are transmitted via conductors 38 to readout electronics 40, as described in P. Fischer et al., IEEE Trans. Nucl. Sci. NS-35 (1988), p. 432 onward, the disclosure of which is incorporated herein by reference. The electronic information from detector 10 is preferably computer processed to obtain values for integral charge and for center of gravity, using known methods and a suitable computer such as a Microvax II, commercially available from Digital Equipment Corporation, where it is stored and processed for data analysis.

It is appreciated that the structure downstream of the photocathode 20 is an electron multiplier. Typically, the photocathode 20 receives a negative voltage via a conductor 42, which is coupled to a voltage source (not shown) via an insulative connector 44. In such a case, the pre-amplification stage 22 is also defined by a mesh electrode 46, which typically is maintained at a desired voltage by means of a conductor 48 coupled to a voltage source (not shown) via an insulative connector 50.

Typical voltages and gap separations at these stages for a typical gas pressure of 20 Torr are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
pre-amplification	3.5	300
first transfer	3.5	150
amplification	3.5	300
second transfer	3.5	100

A preferred level of potential for the readout electrodes 36 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20 and for the respective electrodes 46, 52, 54, and 36 of each stage are:

-2160 V, -1360 V, -1200 V, -400 V, and 0 V.

The gas here and in the embodiments of the present invention shown in Figs. 1B - 1I may comprise any suitable gas which, at relatively low pressure, is non-aging and provides high gain (i.e. high amplification). Typical gases having these characteristics are: dimethylether, isobutane, CF_4 , CH_4 , C_2H_6 , methylal, alcohols such as isopropanol and ethyl alcohol, and mixtures of any of the above.

The additional mesh electrodes 52 and 54 each receive an appropriate voltage supply via corresponding conductors and connectors (not shown). The mesh electrodes are typically formed of stainless steel wires of 50 micron diameter, defining square openings of 500 micron side length. A typical configuration of mesh electrodes 46, 52 and 54 is illustrated in Fig. 3A. These meshes are commercially available from Bopp AG, Bachmannweg 20, CH-8046 Zurich, Switzerland.

Reference is now made to Fig. 1B, which illustrates an alternative embodiment of the invention employing a different type of electron multiplier. The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A and therefore similar elements thereof are indicated by identical reference numerals.

In the embodiment of Fig. 1B, an electron multiplier having a pre-amplification stage 60, a transfer stage 62 and an amplification stage 64 is employed.

Typical voltages and gap separations at these stages for a gas pressure of 20 Torr are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
pre-amplification	3.5	300
transfer	3.5	30
amplification	3.5	800

A preferred level of potential for the readout electrodes 36 is 0 V. In such a case, the preferred levels of potential for the photocathode 20 and for the respective electrodes 65, 52 and 36 of each stage are:

-1680 V, -880 V, -800 V, and 0 V.

According to a preferred embodiment of the present invention, one of the mesh electrodes, preferably electrode 52, between the transfer stage and the amplification stage, receives a selectively changeable voltage provided by a voltage source (not shown) via a switch 66, such as an HV 1000 Pulser, commercially available from DEI, 2301 Research Blvd., Suite 101, Fort Collins, Colorado, USA. Typically, two voltage levels are provided. This arrangement enables mesh electrode 52 to act as a gate, having defined open and closed positions thereof, corresponding to the two voltage levels, thereby determining whether the electrons from the pre-amplification stage reach the amplification stage. Another function of the gate is to substantially prevent positive ions from drifting back to the photocathode and causing damage thereto. Alternatively, the gating function may be eliminated.

Where gating is employed the typical voltages and gap separations at the various stages for a gas pressure of 20 Torr are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
pre-amplification	3.5	300
transfer	3.5	30 (gate open) -20 (gate closed)
amplification	3.5	300 (gate open) 900 (gate closed)

A preferred level of potential for the readout electrodes 36 is 0. In such a case, the preferred levels of potential for the photocathode 20 and for the respective electrodes 65, 52 and 36 of each stage are:

gate open: -1680 V, -880 V, -800 V, and 0 V
gate closed: -1680 V, -380 V, -900 V, and 0 V.

It is noted that in the embodiment of Fig. 1B, the amplification stage causes the avalanche electrons to be collected directly at the pad electrodes 36.

Reference is now made to Fig. 1C, which illustrates yet another embodiment of X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. In this embodiment yet another type of electron multiplier is employed. Here the electrons emitted by the photocathode 20 initially pass through a transfer stage 70 and are subsequently amplified in a plurality of stages identical to that illustrated in Fig. 1A.

There is also provided over the pad electrodes 36 an insulative layer 72, typically formed of epoxy laminate and of thickness 200 microns. Over insulative layer 72, there is provided a resistive layer 74, typically formed of graphite, or of a polymer paste, commercially available from Minico/Ashai Chemical of America, 50 North Harrison Ave., Congres. N.Y., USA. Resistive layer 74 has a typical resistivity of 10 MOhm/square. This structure allows operation of the photocathode at zero potential with the pad electrodes 36 at zero potential as well.

The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A and therefore, similar elements thereof are indicated by identical reference numerals.

Typical voltages and gap separations at these stages for a gas pressure of 20 Torr are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
transfer 1	3.5	100
pre-amplification	3.5	300
transfer 2	3.5	80
amplification	3.5	800
transfer 3	3.5	400

A preferred level of potential for the photocathode 20 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20, for the electrodes 75, 76, 77 and 78 and for the resistive layer 74, respectively, are:

0 V, 100 V, 900 V, 980 V, 1780 V, and 2180 V.

Reference is now made to Fig. 1D, which illustrates yet another embodiment of X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. In this embodiment yet another type of electron multiplier is employed, having a pre-amplification stage 80, first and second transfer stages 82 and 84, an amplification stage 86, and a third transfer stage 88.

Preferably there is provided a mesh electrode 52 between the second transfer and the amplification stages, which receives selectively changeable voltage via switch 66 and which consequently acts as a gate, as described hereinabove in connection with Fig. 1B.

Typical potentials across each stage and gap separations for each stage, for a gas pressure of 20 Torr

are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volts)</u>
pre-amplification	3.5	300
transfer 1	3.5	80
transfer 2	3.5	80 (gate open) -20 (gate closed)
amplification	3.5	300 (gate open) 900 (gate closed)
transfer 3	3.5	400

A preferred level of potential for the photocathode 20 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20, for the electrodes 90, 92, 92 and 94 and for resistive layer 74 are:
gate open: 0 V, 800 V, 880 V, 960 V, 1760 V, and 2160 V
gate closed: 0 V, 800 V, 880 V, 860 V, 1760 V, and 2160 V.

There is also preferably provided an insulative layer 72 and a resistive layer 74 which may be identical to the respective layers 72 and 74 of Fig. 1C.

The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A, and therefore, similar elements thereof are indicated by identical reference numerals.

Reference is now made to Fig. 1E, which illustrates yet another embodiment of X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. In this embodiment yet another type of electron multiplier is employed, having a first transfer stage 100, a preamplification stage 102, an amplification stage 104 and a second transfer stage 106. Typical potentials across each stage and gap separations for each stage, for a gas pressure of 20 Torr are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volts)</u>
transfer 1	3.5	80
pre-amplification	3.5	300
amplification	3.5	800
transfer 2	3.5	400

A preferred level of potential for the electrodes 110 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20 and for the respective electrodes 101, 103, 105 and 110 of each stage are:
-2080 V, -2000 V, -1200 V, -400 V, and 0 V.

According to a preferred embodiment of the present invention, one of the mesh electrodes, preferably electrode 101, between the first transfer stage 100 and the preamplification stage 102, receives a selectably changeable voltage from a voltage source (not shown) via a switch 107, such as an HV 1000 Pulser, commercially available from DEI, 2301 Research Blvd., Suite 101, Fort Collins, Colorado, USA. Typically, two voltage levels are provided. This arrangement enables mesh electrode 101 to act as a gate, having defined open and closed positions thereof, corresponding to the two voltage levels. The function of the gate is to prevent positive ions from drifting back to the photocathode 20 and causing damage thereto, when the gate is closed. Alternatively, the gating function may be eliminated.

If gating is employed the typical voltages and gap separations at the various stages for a gas pressure of 20 Torr are as follows:

STAGE	GAP THICKNESS (mm)	VOLTAGE DIFFERENCE (volt)
transfer 1	3.5	50 (gate open)
	3.5	20 (gate closed)
pre-amplification	3.5	300 (gate open)
	3.5	900 (gate closed)
amplification	3.5	300
transfer 2	3.5	400

15 A preferred level of potential for the electrodes 110 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20 and for the respective electrodes 101, 103, 105 and 110 of each stage are:

gate closed: -2080 V, -2100 V, -1200 V, -400 V and 0 V.

gate open: -2080, -2000, -1200, -400, 0V.

20 Electrode array 34 of Fig. 1A is here replaced by a readout electrode assembly 108 shown in detail in Fig. 3D, typically comprising a first array of strip electrodes 110, typically in mutually parallel orientation, a generally planar insulating element 112 and a second array of strip electrodes 114, typically in mutually parallel orientation and being generally perpendicular to the orientation of strip electrodes 110.

25 Electrode arrays 110 and 114 may take any suitable form such as a thin copper layer deposited on both sides of insulating element 112. The width of an electrode strip 110 is typically approximately 1-3 mm and the separation between adjacent strips is typically approximately 0.2 - 0.5 mm. The width of and separation between electrode strips 114 may be the same. The insulating element 112 may be formed of any suitable material such as epoxy laminate with a typical thickness of 200 microns.

30 Any suitable method may be employed to read out the information from the strip electrode arrays. The readout electronics 40 of previous embodiments is here replaced by readout electronics 116, such as described in V. Radeka and R.A. Boie, Nucl. Instrum. Methods 178 (1980) 543, the disclosure of which is incorporated herein by reference. Connectors 38 are here replaced by appropriate connectors (not shown) between strip electrode arrays 110 and 114, and readout electronics 116. The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A.

35 Reference is now made to Fig. 1F, which illustrates yet another embodiment of X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. In this embodiment yet another type of electron multiplier is employed, having a preamplification stage 120, first, second and third transfer stages 122, 124 and 126, and an amplification stage 128.

40 There are also typically provided two gate electrodes 130 and 132 on both sides of the second transfer stage which may be identical to gate electrode 52 of Fig. 1B. Electrodes 130 and 132 receive selectably changeable voltages via switches 134 and 136 respectively. The voltages provided via switches 134 and 136 are preferably approximately -50 V and +50 V, respectively.

Typical potentials across each stage and gap separations for each stage, for a gas pressure of 20 Torr are as follows:

45

50

55

	<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
	pre-amplification	3.5	300
5	transfer 1	3.5	30 (gate open)
	transfer 1	3.5	30 (gate open)
			130 (gate closed)
10	transfer 2	3.5	80 (gate open)
			-20 (gate closed)
15	transfer 3	3.5	30 (gate open)
			130 (gate closed)
	amplification	3.5	300

20

A preferred level of potential for the electrode 110 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20 and for the respective electrodes 137, 130, 132, 138 and 110 of each stage are:

25 gate open: -1840 V, -1040 V, -960 V, -880 V, -800 V, and 0 V
 gate closed: -1840 V, -1040 V, -910 V, -930 V, -800 V, and 0 V.

Any suitable method may be employed to read out the information from the strip electrode arrays. The readout electronics 40 of previous embodiments is here replaced by readout electronics 116, as in Fig. 1E. Connectors 38 are here replaced by appropriate connectors (not shown) between strip electrode arrays 110 and 114, and readout electronics 116, again as in Fig. 1E. The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A, and therefore, similar elements thereof are indicated by identical reference numerals.

Reference is now made to Fig. 1G, which illustrates yet another embodiment of X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. In this embodiment yet another type of electron multiplier is employed, having a preamplification stage 140, transfer stage 142, an amplification stage 144 and an insulative gap 145.

The electrode 146 between the preamplification stage and transfer stage may be identical to the electrode 52 of Fig. 1A. There are also provided electrode assemblies 148 and 150 defining the amplification stage 144 which are each preferably of the type illustrated in Fig. 3B. Unlike in the previous embodiments in which readout electrode assemblies are provided, in the present embodiment, electrode assemblies 148 and 150 are directly read by readout electronics 116.

Referring now to Fig. 3B, each electrode assembly 148 and each electrode assembly 150 comprises a generally planar insulating element 152, a plurality of wires 154 having a generally mutually parallel orientation and being soldered at each end to corresponding pluralities of soldering taps 156 and 158.

The generally planar insulating element 152 may be formed of any suitable material such as epoxy laminate. The wires may be Tungsten gold-plated and may be of a diameter of approximately 20 - 100 microns. Suitable wires are commercially available from Lumalamp Corporation, Sweden. The spacing between wires may be approximately 1-2 mm.

Referring again to Fig. 1G, there is provided readout electronics 116 which may be identical to readout electronics 116 of Fig. 1E. Readout electronics 116 is connected to taps 158 by suitable connectors (not shown).

The orientation of the parallel wires 154 of electrode assembly 148 is preferably generally perpendicular to the parallel wires 150.

Typical potentials across each stage and gap separations for each stage, for a gas pressure of 20 Torr are as follows:

15

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
pre-amplification	3.5	300
transfer	3.5	30
amplification	3.5	300

A preferred level of potential for the electrode 150 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20 and for the respective electrodes 146, 148 and 150 of each stage are: -1680 V, -880 V, -800 V, and 0 V.

The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A, and therefore, similar elements thereof are indicated by identical reference numerals.

Reference is now made to Fig. 1H, which illustrates yet another embodiment of X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. In this embodiment yet another type of electron multiplier is employed, having a first transfer stage 170, a preamplification stage 172, a second transfer stage 174, and first and second amplification stages 176 and 178, and an insulative gap 179.

The electrodes 180 and 182 which define the preamplification stage 172 may be identical to the mesh electrode of Fig. 3A. There are also provided electrode assemblies 184, 186 and 188, defining the first and second amplification stages, which may be identical to electrode assemblies 148 and 150 of Fig. 1G. Electrode assemblies 184, 186 and 188 may be arranged such that the respective wires thereof define any desired angle between them. For example, the wires of assemblies 184 and 186 may be parallel to one another, whereas the wires of assembly 188 may be perpendicular to the wires of the other two.

Typical potentials across each stage and gap separations for each stage, for a gas pressure of 20 Torr are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
transfer 1	3.5	100
pre-amplification	3.5	300
transfer 2	3.5	100
amplification 1	3.5	300
amplification 1	3.5	600

A preferred level of potential for the photocathode 20 is 0 volts. In such a case, the preferred levels of potential for the photocathode 20 and the respective electrodes 180, 182, 184, 186 and 188 of each stage are:

0 V, 100 V, 900 V, 1000 V, 1800 V, and 2400 V.

Any suitable method may be employed to read out the information from the electrode assemblies 184, 186 and 188 (or, alternatively, from assemblies 186 and 188 only). The readout electronics 116 of the present embodiment may be identical to readout electronics 116 of Fig. 1E. Appropriate connectors (not shown) are provided between the electrode assemblies 184, 186 and 188, and readout electronics 116. It is appreciated that, due to this arrangement, a separate readout electrode assembly need not be provided.

The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A, and therefore, similar elements thereof are indicated by identical reference numerals.

Reference is now made to Fig. 1I, which illustrates yet another embodiment of X-ray detector constructed and operative in accordance with a preferred embodiment of the present invention. In this embodiment yet another type of electron multiplier is employed, having a preamplification stage 200, first, second and third transfer stages 202, 204 and 206 respectively, an amplification stage 208, and an insulative gap 209. The photocathode 20 is followed by three mesh electrodes 210, 212 and 214 which may be identical to electrode 52 of Fig. 1A, which is illustrated in detail in Fig. 3A. The three mesh electrodes

are followed by three electrode assemblies 220, 222 and 224 which define the amplification stage 208 and which are each preferably of the type illustrated in Fig. 3B. However, in the present embodiment, preferred characteristics of the wires of the electrode assemblies are as follows:

Assemblies 220, 224: approximately 50-100 micron diameter wires, approximately 0.5-1 mm apart;

Assembly 222: approximately 20-50 micron diameter wires, approximately 1-2 mm apart.

Electrodes 212 and 214 on both sides of the second transfer stage 204 act as gate electrodes in the present embodiment, receiving selectably changeable voltages via switches 226 and 228 respectively. The voltages provided via switches 226 and 228 are preferably approximately -50 V and +50 V respectively.

Typical potentials across each stage and gap separations for each stage, for a gas pressure of 20 Torr are as follows:

STAGE	GAP THICKNESS (mm)	VOLTAGE DIFFERENCE (volt)
pre-amplification	3.5	800
transfer 1	3.5	80 (gate open) 130 (gate closed)
transfer 2	3.5	80 (gate open) -20 (gate closed)
transfer 3	3.5	80 (gate open) 130 (gate closed)
amplification:		
first gap	3.5	600
second gap	3.5	-600

A preferred level of potential for the photocathode 20 is 0 volts. In such a case, the preferred levels of potential for the respective electrodes 210, 212, 214, 220, 222 and 224 of each stage are:

gate open: 800 V, 880 V, 960 V, 1040 V, 1640 V, and 1040 V

gate closed: 800 V, 930 V, 910 V, 1040 V, 1640 V, and 1040 V

Any suitable method may be employed to read out the information from the electrode assemblies 220, 222 and 224 (or, alternatively, from assemblies 220 and 224 only). The readout electronics 116 of the present embodiment may be identical to readout electronics 116 of Fig. 1E. Appropriate connectors (not shown) are provided between the electrode assemblies and readout electronics 116. It is appreciated that, due to this arrangement, a separate readout electrode assembly need not be provided.

Electrode assemblies 220, 222 and 224 may be arranged such that the wires thereof define any desired angle between them. For example, the wires of assemblies 220 and 224 may be parallel to one another, whereas the wires of assembly 222 may be perpendicular to the wires of the other two.

The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A, and therefore, similar elements thereof are indicated by identical reference numerals.

Reference is now made to Figs. 2A-2B which illustrate an X-ray photon detector combined with an optical sensor constructed and operative in accordance with preferred embodiments of the present invention. The X-ray detector 10 may comprise any suitable X-ray detector such as those shown and described hereinabove with reference to Figs. 1A-1I, but with the following exceptions:

A. The readout (referenced 10 in Figs. 1A-1D and 116 in Figs. 1E-1I) is here replaced by an optical readout system, referenced generally as 234 and 236 in Figs. 2A and 2B respectively and described in detail hereinbelow; and

B. There is provided an optical window 238 which is operative to extract the light from the electron and light multiplier 10. Any suitable commercially available UV transparent window 238 may be used, such as Quartz Suprasil-1 available from Heraeus, Hanau, West Germany. The thickness is determined as a function of the dimensions of the detector's active area. For example, if the active area is of dimensions

20 x 20 mm; the thickness of the optical window 238 should be approximately 15 mm.

D. The gas comprises any suitable light emitting gas or gas mixture which does not substantially inhibit electron avalanche such as the gas mixtures disclosed in D. Sauvage, A. Breskin & R. Chechik, "A systematic study of the emission of the light from electron avalanches in low pressure TEA and TMAE gas mixtures", Nucl. Instrum. Methods, A275, (1989), p. 351 onwards, and in A. Breskin et al., "A Three Stage Gated UV Photon Gaseous Detector With Optical Imaging", Nucl. Instrum. Methods A 286 (1990) p. 251 onwards, the disclosures of which are incorporated herein by reference. The gas pressure may be 20 Torr, as in previous embodiments.

The two documents incorporated by reference in the previous paragraph report results of operation of an avalanche gaseous amplification detector, containing a gas mixture comprising approximately 0.1 - 5 Torr of TMAE vapor or approximately 10 - 50 Torr of TEA vapor. These gas mixtures were found to emit light during the avalanche amplification process, as a result of the excitation of the gas molecules. The amount of light emitted was found to be directly proportional to and thus indicative of the number of electrons in the avalanche. Specifically, approximately 0.1 to 5 photons were found to be emitted per avalanche electron, depending on the particular composition of the gas and on the operation conditions of the amplification structure.

For example, using a gas mixture of 80% C₂H₅, 20% Ar at 100 Torr, further comprising 5 Torr of TMAE, and using the apparatus of Fig. 2A, wherein the reduced electric field in the second amplification stage 246 is 20 V/cm Torr, the mean number of photons emitted per avalanche electron was found to be 1.5. When TEA gas mixtures were used, even higher mean values for the number of photons per avalanche electron, were found. Due to the above results, and since the light is emitted at the same location in space at which the charge is produced by the amplification process, localization and quantification of the light spot are equivalent to localization and quantification of the charge.

Referring now specifically to Fig. 2A, there is shown yet another type of electron multiplier having a preamplification stage 240, a transfer stage 242, and first and second amplification stages 244 and 246, and an insulative gap 243. The second amplification stage 246 acts as the main light amplifying element. The features of a typical light amplifying element are described in A. Breskin et al., "A highly efficient low pressure UV-RICH detector with optical avalanche recording," Nucl. Instrum. Methods A 273 (1988), p. 798 onwards, and in A. Breskin et al., "A Three Stage Gated UV Photon Gaseous Detector With Optical Imaging" Nucl. Instrum. Methods A 286 (1990) P. 251 onwards, the disclosures of which are incorporated herein by reference.

The electrodes 245, 247, 248 and 249 defining the four stages referenced hereinabove, with the exception of photocathode 20, may be identical to electrode 52 of Fig. 1A, which is illustrated in detail in Fig. 3A.

Typical potentials across each stage and gap separations for each stage for a gas pressure of 40 Torr are as follows:

STAGE	GAP THICKNESS (mm)	VOLTAGE DIFFERENCE (volt)
pre-amplification	3.5	1100
transfer	3.5	200
amplification 1	3.5	1100
amplification 2	3.5	500

A preferred level of potential for the photocathode 20 is 0 volts. In such a case, the preferred levels of potential for the respective electrodes 245, 247, 248 and 249 of each stage are: 1100 V, 1300 V, 2400 V, and 2900 V.

The optical system 234 recording the information from detector 10 comprises a UV transparent lens 250, such as a FLECTAN 75 Q, commercially available from NYE Optical Company, Spring valley, CA, USA. The image is transferred to a position sensitive optical element 252, such as an array of position sensitive photomultipliers, such as an XP 4702 photomultiplier with a sapphire window, commercially available from Phillips. The information from optical element 252 is received by readout electronics 254, such as that described by G. Comby et al., Nucl. Instrum. Methods A243 (1986), p. 165-172, the disclosure of which is incorporated herein by reference.

The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A, and therefore, similar elements thereof are indicated by identical reference numerals.

Referring now specifically to Fig. 2B, there is shown yet another type of electron multiplier having a first transfer stage 260, a preamplification stage 262, a second transfer stage 264, an amplification stage 266 which acts as the main light amplifying element, and an insulative gap 265. The features of such a light amplifying element in the present embodiment.

The electrodes 267, 268, 269 and 271 defining the four stages referenced hereinabove, with the exception of photocathode 20, may be identical to electrode 52 of Fig. 1A, which is illustrated in detail in Fig. 3A.

Typical potentials across each stage and gap separations for each stage for a gas pressure of 40 Torr are as follows:

<u>STAGE</u>	<u>GAP THICKNESS (mm)</u>	<u>VOLTAGE DIFFERENCE (volt)</u>
transfer 1	3.5	200
pre-amplification	3.5	1100
transfer 2	3.5	200
amplification	3.5	1100

A preferred level of potential for the photocathode 20 is 0 volts. In such a case, the preferred levels of potential for the respective electrodes 267, 268, 269 and 271 of each stage are:

200 V, 1300 V, 1500 V, and 2600 V.

The optical system 236 recording the information from detector 10 comprises an optical taper 270, such as the custom-made taper commercially available from Schott Fibre Optics Inc., Southbridge, MA, USA, which is coupled to the optical window 238 via a wavelength shifter 272, such as p-terphenyl. The optical taper 270 is coupled to an image intensifier assembly 274, such as a BV 2562QX light amplifier coupled to a BV 1833 EG11 light amplifier, both commercially available from Proxitronic of Bensheim, W. Germany. Image intensifier 274 is coupled to a position sensitive optical element 276, such as a CCD camera, typically a 7864FO, commercially available from Thomson - France, which is read out by readout electronics 278, such as Thomson Driving Electronics Kit model TH 79K64 coupled to frame grabber and digitizer DT28531, commercially available from Data Translation of Marlboro, MA, USA. The digitizer output may be supplied for frame analysis to a computer such as a PC/AT, used in conjunction with suitable software such as DT-IRIS, commercially available from Data Translation, Marlboro, MA, USA. Alternatively, the position sensitive optical element 276 and the readout electronics 278 may be replaced by the position sensitive optical element 252 and the readout electronics 254, respectively, of Fig. 2A.

The remainder of the apparatus is essentially identical to that described hereinabove in connection with Fig. 1A, and therefore, similar elements thereof are indicated by identical reference numerals.

Reference is now made to Figs. 4A and 4B, which illustrate X-ray detectors in which the photocathode is planar and is capable of receiving X-ray radiation impinging on either or both sides thereof, constructed and operative in accordance with alternative embodiments of the present invention. It is appreciated that the X-ray photons may impinge upon the photocathode 20 of the detector 10 at any desired angle α . Preferably, however, the angle α will be relatively large, i.e. in the range of approximately 80 to 90 degrees from the perpendicular, to enhance the detection efficiency.

Referring now to Fig. 4A, it is appreciated that X-ray photons may impinge upon the photocathode 20, associated with electron multiplier 300 disposed downstream thereof, from either the upstream side or the downstream side thereof. In Fig. 4A, X-ray photon beam (a) is shown impinging upon the upstream side of the photocathode, whereas the X-ray photon beam (b) is shown impinging upon the downstream side thereof. Electron multiplier 300 creates an electron avalanche 302, read out by a readout system 304, as shown.

Reference is now made to Fig. 4B, which shows that two electron multipliers 306 and 308 may be provided on both respective sides of photocathode 20, which in this embodiment comprises a double side photocathode 20 such as the photocathode assemblies shown in Figs. 6A and 6G. Electron multipliers 306 and 308 each create an electron avalanche, referenced 310 and 312 respectively, amplifying electrons from the photocathode 20. Electron multipliers 306 and 308 are preferably read out separately by readout systems 314 and 316, respectively, as shown. As in Fig. 4A, the X-ray photons may impinge upon the

photocathode 20 from either side thereof.

Reference is now made to Fig. 5 which illustrates an X-ray detector assembly, indicated generally by reference numeral 330, which is constructed and operative in accordance with yet another preferred embodiment of the present invention. Assembly 330 comprises a low-pressure gas filled enclosure 332 including an entrance window 334, typically formed of polypropylene supported on a frame (not shown), similar to the window 14 and frame 16 shown and described with reference to Fig. 1A. However, the assembly 330 comprises a plurality of stacked X-ray detector modules 336, rather than a single such module as in the embodiments of Fig. 1A-1I. Each module may comprise an electron multiplier identical to the various embodiments thereof disclosed with reference to Figs. 1A-1I. According to a preferred embodiment, the modules are arranged in a generally mutually parallel orientation which is at an angle beta of typically 1 to 10 degrees from the X-ray beam impingement direction 338. It is noted that individual windows need not be provided for each individual module 336. Rather, the entire enclosure 332 is a single gas filled enclosure.

Reference is now made to Figs. 6A-6G, which illustrate alternative embodiments of photocathode assemblies useful in the present invention. Referring specifically to Fig. 6A, there is shown a photocathode comprising a metal foil 350 which may be formed of any suitable conducting material such as tantalum, gold, platinum, aluminum, or tungsten, of a thickness depending on the energy of impinging photons. For example, for a gold layer 350 and an X-ray energy of 10 KeV, a typical thickness is approximately 5 microns. For an X-ray energy of 80 KeV, a typical thickness is approximately 15 microns.

Fig. 6B shows a photocathode assembly comprising a thin semiconductive or metal photocathode layer 352 deposited upon an insulative support foil layer 354. Thin layer 352 may be formed of any suitable semiconductive or conducting material such as CuI or gold, of a suitable thickness which depends on the energy of the impinging photons. For example, for a CuI layer 352 and an X-ray energy of 10 KeV, a typical thickness is approximately 1 micron. If the X-ray energy is 80 KeV, a typical thickness is approximately 30 microns. The insulative support foil layer 354 may be formed of any suitable electrically insulative, low X-ray absorbing material such as polypropylene, Parylene M, Kapton, Mylar, Aclar or Nylon, of suitable thickness. For example, for an X-ray energy of 10 KeV, a typical thickness is in the range of 5-50 microns.

Fig. 6C shows a photocathode assembly comprising a nonconductive (insulating or semi-conducting) photocathode layer 356 deposited upon a thin metal support layer 358. Photocathode layer 356 may be formed of any suitable nonconductive material such as CsI or CuI of a suitable thickness which depends on the energy of impinging photons. For example, for a CsI photocathode layer 356 and an X-ray energy of 10 KeV, a typical thickness is approximately 1.5 microns. For an X-ray energy of 80 KeV, a typical thickness is approximately 45 microns. The support layer 358 may be formed of any suitable metal such as aluminum, gold or copper, of suitable thickness. For example, for a gold layer 358 and an X-ray energy of 10 KeV, a typical thickness is 5-10 microns.

Fig. 6D shows a photocathode assembly comprising a thin insulative support layer 360 followed by a thin conductive layer 362 and a nonconductive photocathode layer 364. Support layer 360 may be identical to support layer 354 of Fig. 6B. Conductive layer 362 may be formed of any suitable material such as aluminum, gold or Nichrome of suitable thickness. For example, a gold layer 362 is typically approximately 1 micron thick. Photocathode layer 364 may be identical to photocathode layer 356 of Fig. 6C.

Fig. 6E shows a photocathode assembly comprising a metal support layer 366 followed by a low density nonconductive photocathode layer 368. Metal support layer 366 may be identical to support layer 358 of Fig. 6C. Photocathode layer 368 may be formed of a layer of fluffy (low density) CsI, typically with a density of approximately 1-3% of the bulk density of CsI and being of a suitable thickness. For example, for an X-ray energy of 5 KeV, a typical thickness is in the range of 1000 micrograms/cm². Details of a preferred material suitable for photocathode layer 368 are provided in C. Chianelli et al., Nucl. Instrum. Methods A 273 (1988) p. 245-256, and in "Quantum Efficiency of Cesium Iodide Photocathodes at Soft X-ray and Extreme Ultraviolet Wavelengths", by M.P. Kowalski et al. Applied Optics Vol. 25, No. 14 (15 July 1986), pages 2440-2446, the disclosures of which documents are incorporated herein by reference.

Fig. 6F shows a photocathode assembly comprising a support layer 370 followed by a nonconductive photocathode layer 372 and a thin metal layer 374. Support layer 370 may be identical to support layer 358 of Fig. 6C. The photocathode layer 372 may be identical to photocathode layer 356 of Fig. 6C. The thin metal layer 374 may be formed of any suitable material such as Nichrome, Aluminum, or Gold having a thickness of 0.05 - 1 micron.

Fig. 6G shows a photocathode assembly 376 corresponding to the photocathode assembly of Fig. 6D but being double-sided. It is appreciated that any of the photocathode assemblies of Figs. 6B-6F may similarly be provided in double-sided form. Photocathode assembly 376 comprises a thin insulative support layer 380 sandwiched between a first thin conductive layer 382 followed by a nonconductive photocathode

It will be appreciated by persons skilled in the art that the present invention is not limited by what has been particularly shown and described above. The scope of the present invention is defined only by the claims which follow:

New Approaches to Spectroscopy and Imaging of Ultrasoft-to-hard X-rays

A. Breskin, R. Chechik,¹ V. Dangendorf,² S. Majewski,³ G. Malamud,
A. Pansky and D. Vartsky⁴

Department of Physics, The Weizmann Institute of Science
76100 Rehovot, Israel

Abstract

We propose new techniques of X-ray spectroscopy and imaging, based on the use of low-pressure multistep gaseous electron multipliers. Ultrasoft X-rays are detected by counting single electron clusters induced in the gas. X-ray induced UV-photons in Gas Scintillation Chambers are read out with wire chambers coupled to CsI photocathodes. X-rays converted in foil-electrodes are imaged by fast multistep avalanche electron multipliers.

We discuss the advantages of the various techniques and present experimental results and Monte Carlo simulations.

presented at the
2nd London Conference on Position Sensitive Detectors
September 1990, Imperial College, London

To be published in Nuclear Instruments and Methods in Physics Research A

² Present address: Institute für Kernphysik, Frankfurt, W. Germany

³ Present address: CEBAF, Physics division, Newport News, VA, USA

⁴ Soreq Nuclear Research Center, Yavne 70000, Israel

layer 384 on one side, and a second thin conductive layer 386 followed by a second photocathode layer 388, on the other side. Thin insulative support layer 380 may be identical to support layer 360 of Fig. 6D. First and second thin conductive layers 382 and 386 may be identical to conductive layer 362 of Fig. 6D. Photocathode layers 384 and 388 may be identical to photocathode layer 364 of Fig. 6D.

The photocathode assembly in Fig. 6A is particularly useful in high energy X-ray applications (in the range of approximately 50 - 500 KeV). The photocathode assemblies in Figs. 6B-6D and 6F-6G are particularly useful in the low and medium energy range (approximately 6 - 50 KeV). The photocathode assembly in Fig. 6E is particularly useful in the very low energy range (approximately 0.1 - 6 KeV).

It is noted that the features shown and described in connection with various drawings, such as the presence of a gate, the presence of a resistive layer, the type of readout electrode, and the choice of readout method may be combined in any suitable combination in accordance with the present invention.

The results of an experiment demonstrating the efficiency of the X-ray detection apparatus shown and described herein, relative to state of the art X-ray detectors are now described.

In the experiment, performance of an X-ray detector constructed and operative in accordance with the present disclosure and including the preferred embodiment of photocathode shown and described above with reference to Fig. 6C was compared to the performance of an X-ray detector which was identical except that the photocathode was as shown and described above with reference to Fig. 6A.

The performance of the detector including the photocathode of Fig. 6A is seen in Fig. 7A. The performance of the detector including the photocathode of Fig. 6C is seen in Fig. 7B. As is obvious from a comparison of the two figures, the quantum efficiency of the photocathode of Fig. 6C considerably exceeds the quantum efficiency of the photocathode of Fig. 6A. Specifically, it was found that when the photocathode of Fig. 6C was employed, substantially all (100%) absorbed X-ray photons were detected by the device.

Also, the timing response of an X-ray detector including the photocathode of Fig. 6C was measured using a UV radiation source rather than an X-ray radiation source. The timing was found to be approximately 4 nanoseconds for a single electron event and less than one nanosecond for a multielectron event. It is believed that this result is approximately 100 times superior to results obtained using state of the art X-ray detectors. For example, fast scintillators have timing of a few microseconds.

Details of the above experiment are provided in an article submitted to the journal entitled Nuclear Instruments and Methods in Physics Research, the text of which is appended hereto and is referenced Appendix A.

Results of an experiment demonstrating the relatively high detection resolution achieved by the apparatus shown and described herein are reported in the following publication, the disclosure of which is incorporated herein by reference:

"High Accuracy Imaging of Single Photoelectrons by Low-Pressure Multistep Avalanche Chamber Coupled to a Solid Photocathode" by A. Bräskén and R. Chechik, Nuclear Instruments and Methods in Physics Research 227, (1984) 24-28.

In this experiment, the detection resolution was found to be of the order of 0.2 mm.

It is appreciated that the X-ray detection apparatus and methods shown and described hereinabove are general and have a very broad range of applications. A medical radiography application is now discussed, it being appreciated that this application is intended to be merely exemplary of the possible applications and is not intended to be limiting.

The above description is applicable to an X-ray medical diagnostic method including the steps of:

radiating a subject to be diagnosed with X-ray radiation; and
employing an X-ray detector of the type shown and described above in order to perform radiography by detecting the X-ray radiation.

For medical applications, a crucial consideration is to minimize the dosage of radiation. Therefore, it is believed that a preferred embodiment of X-ray detector employed for medical purposes is one which is sensitive to a relatively small amount of radiation, such as the embodiments of Fig. 4B or 5. It is believed to be most preferable to employ an embodiment of X-ray detector which combines the double-sided characteristic of the embodiment of Fig. 4B with the relatively small angle between the photocathode surface and the direction of radiation provided in the embodiment of Fig. 5.

The disclosure of the present invention is also believed to have industrial applications in monitoring and controlling dynamic industrial processes such as lubrication of mechanical parts and flows of fluids through mechanical systems. The disclosure of the present invention is also believed to be applicable to screening of static objects such as screening of luggage at air facilities to detect weapons and narcotics. As described above, a particular feature of the apparatus and methods of X-ray detection disclosed herein is the relatively high detection resolution achieved thereby. This feature is particularly important in industrial and security applications.

1. Introduction

The use of gaseous X-ray detectors is widespread in many fields of basic and applied research. Much of the progress in this domain was motivated in the past few years by the availability of high intensity Synchrotron Radiation facilities. Considerable effort is being channeled towards the development of high rate, fast and accurate imaging devices, enabling, for example, the study of time resolved phenomena. Another domain of interest is in detectors with an improved energy resolution for the spectroscopy of ultrasoft-to-mid energy X-rays. The main applications here are in material science, astrophysics, plasma diagnostics and atomic physics. Fast and efficient imaging devices are required for the detection of hard X-rays in industrial and medical applications.

In the present article we review some new approaches, recently investigated, to X-ray spectroscopy and imaging over a broad energy range. The proposed techniques are based on the use of low-pressure multistep gaseous electron multipliers. Low-pressure multistep chambers^{1,2)} (LPMSC) provide high gain ($> 10^7$ for single electrons), fast response, good localization, high rate capability, low sensitivity to background radiation, reduced aging, and gating capabilities. Consequently, this type of electron multiplier finds many applications in the fields of detection of low-ionization radiation^{3,4)} and single electrons. Photosensitive LPMSC's^{5,6)} efficiently detect UV-photons in Čerenkov Ring Imaging detectors⁷⁾ (RICH) and UV-photons emitted from BaF_2 scintillation in application to particle physics⁸⁾ and medicine⁹⁾. Single electron cluster counting methods are developed for particle identification by their specific ionization¹⁰⁾ and for soft X-ray spectroscopy.

Primary Ionization Cluster Counting (PICC) is performed by coupling a multistep electron multiplier to a large low-pressure, low-field, conversion and drift volume, in which particles or soft X-rays induce trails of primary charges. In the case of ultra-soft X-rays

(0.1-1 keV), due to the large diffusion and the relatively long range of photoelectrons, primary charges are efficiently separated in space and time. They are individually multiplied and counted and their number is proportional to the X-ray energy. The resulting energy resolution competes with that of gas scintillation counters.

Another method investigated in the present study is a 3D X-ray camera for the spectroscopy and imaging of photon quanta in the energy range of 30-100 keV. It is based on a high-pressure Xe-filled gas scintillation chamber, from which the emitted UV-photons ($\bar{\lambda}=170$ nm) are converted on a CsI photocathode coupled to a LPMSC imaging electron multiplier. The quantum efficiency (QE) of the UV-detector is of the order of 10%. The X-rays are localized with an accuracy of 2 mm. The device is fast and allows background reduction by pulse-shape analysis.

Fast X-ray imaging at high photon flux, can be achieved when coupling thin solid photocathodes to LPMSC electron multipliers. The high rate capability is derived from reduced space charge effects due to the fast ion collection and the low charge density of the electron avalanche. Possible aging due to high total deposited ion charge can be eliminated by the use of DME gas¹¹⁾. The effective energy range of the detector depends on the choice of the photocathode converters.

In this article, we describe each of the various detection methods investigated. Experimental results, some of which are of a preliminary nature, and Monte Carlo simulations are presented, and possible applications are discussed.

2. Spectroscopy of ultrasoft X-rays with Primary Ionization Cluster Counting

High-resolution detection of soft-X-rays is required in materials science for surface analysis with electron microprobes. In this domain, in parallel to the conventional surface

image, one detects characteristic X-rays emitted by the impact of the electron beam with the analyzed sample surface. This allows the correlation of topography with chemical composition. Of particular importance is the energy range of 0.1–1 keV corresponding to characteristic X-rays of light elements such as B, C, O, N etc. The standard technique employs cryogenic Si-Li detectors separated from the high-vacuum chamber of the analyzed sample by a thin Be window. This window, usually about 10 μm thick, introduces severe limitations since it absorbs most of the characteristic radiation of elements up to Na. Room temperature Si-Li detectors, operating without Be windows, are ineffective below 400 eV, due to poor signal-to-noise ratio.

Alternative methods such as Gas Scintillation Proportional Chambers (GSPC)¹²⁾ or electron-counting with proportional counters¹³⁾ were proposed. Both types of detectors have the inconvenience of operating at atmospheric pressure with the drawbacks mentioned above. Gas scintillation at low-pressure was attempted but it is inadequate for this application because the light yield decreases linearly with pressure¹⁴⁾. We have recently employed a thin-window LPMSC, operating in a proportional mode and coupled to a conversion volume a few millimeters wide, for the detection of C-K X-rays of 279 eV. An energy resolution of 53% FWHM was obtained at ~ 3 Torr. A detailed description of this device is found in ref. 15.

The primary ionization cluster counting (PICC) at low gas pressures may well be a suitable method for the spectroscopy of ultrasoft X-rays. It is well known that the energy resolution of a gaseous detector depends on several factors and to first order it may be written as

$$\left(\frac{\sigma(E)}{E}\right)^2 = \frac{F}{\bar{N}_p} + \frac{f}{\bar{N}_p} \quad (1)$$

where \bar{N}_p is the mean number of primary ion pairs.

The first term contains the Fano factor F which describes the statistical fluctuations in the primary ionization process. The second term contains the function f which is the variance of the gas amplification A for a single electron ($f = (\sigma(A)/\bar{A})^2$) and represents the contribution due to charge amplification in proportional detectors. It is a monotonic function of the gain and has values between 0 and 1. However, f is significantly smaller than 1 only at very low charge gains, typically $A \leq 100$.

In the case of gas scintillation counters the second term in (1) is replaced by $(1+f)/\bar{N}_e$, \bar{N}_e being the mean number of detected photoelectrons in the UV-detector. This term represents the contribution due to the statistics of photon detection and of the photoelectron amplification process. In all practical detectors, using either charge amplification in proportional mode or light amplification in scintillation mode, the secondary amplification statistical fluctuations contribute considerably to the deterioration of the energy resolution.

The only method which avoids such additional broadening, and depends only on the primary electron statistics, is the electron counting method. This method was attempted for soft X-rays at atmospheric pressure¹³⁾, counting light pulses associated with electron avalanches. We advocate the use of the low-pressure operation mode which has the following advantages:

- The possibility of using thin windows allows for a more efficient coupling to the radiation source (usually in vacuum).
- the primary clusters are better separated and more efficiently counted.
- there is no need to reduce the drift field to values that may provoke recombination, in order to diffuse and separate the primary charges.

The choice of a counting gas in the present method is somewhat easier than in GSC's,

where highly purified Xe or its mixtures with other noble gases are employed. We may employ a gas mixture which has a lower Fano factor, as compared to Xe ($F=0.12^{15}$), and at the same time is a good Penning mixture providing a higher value for \bar{N}_p . Some good candidates are $Ar + 0.5\% C_2H_2$ or $He + 0.5\% CH_4^{17}$ which may yield an energy resolution at FWHM of about $\frac{\Delta E}{E} = 10\%/\sqrt{E}$. This resolution is better, by about a factor of two, than that obtainable in Xe-filled gas scintillation detectors¹²). In addition the present method does not require complex purification systems as is the case with GSC's.

Our prototype detector is presented schematically in Fig. 1. The detector, of circular geometry and active area of 50 cm², has a 20 cm long conversion region followed by a double-stage, parallel grid, amplification structure. All the electrodes are made of stainless steel mesh, 50 μ m diameter and 500 μ m cell size. The mesh is supported by epoxy resin frames. The conversion volume is made of a Delrin cylinder covered on the inside with a Kapton layer with etched copper strips. The strips are 3 mm wide and 5 mm apart. A resistor chain provides a constant potential gradient. The X-ray source is housed in a vacuum cell, separated from the detector by a 20 mm diameter, 60 μ g/cm² thick, polypropylene foil, placed close to the end-cup mesh of the drift cell. We used a commercial ²⁴⁴Cm α -induced X-ray source with changeable targets¹³). Soft X-rays which enter the conversion volume produce a trail of primary charges. For example, 279 eV C-K induced primary electrons typically extend over 1 mm at a gas pressure of 10 Torr. The electrons drift at low-field of about 0.5 V/cm-Torr, towards the first 3 mm wide parallel-plate amplification gap. Due to the long drift path under high diffusion the original electron swarm expands to a size of a few cm, leading to a pulse trail duration of a few μ s. Each primary electron is independently amplified. A fraction of the preamplified avalanche is transferred through a low-field transfer region to a second parallel grid amplification element which provides the

signals for electron counting and, as an option, for localization. These signals are shaped by a fast amplifier and fed into a digitizer. Each event is stored in a PC computer as an array of 2K elements, 10 bits each.

Fig. 2 gives examples of events induced by C-K 279 eV photons in 3 Torr of a C_2H_5/Ar (80/20) gas mixture. The X-ray photons are absorbed in the first few cm of the conversion volume and produce on the average 10.7 primary charges. The primary electron swarm expands, due to the diffusion, over 1-2 cm (2-4 μ sec). The individual electron signals have a full width of about 50 ns. Cosmic events have different cluster-density and total time spread and can be easily discriminated against.

The primary cluster counting can be performed with fast discriminators followed by proper pulse integrators¹⁰⁾. However, an analog pulse digitization, followed by a software-based cluster counting, is more adequate for the systematic study of the PICC method. We used the correlation method^{19,20)}, demonstrated in fig. 3, which provides automatic peak counting by scanning the data with a "search-function" of known shape and recording the correlation between the data and the "search-function". This method is quite sensitive and is capable of recognizing peaks which are not fully separated, as is seen in fig. 3. Fig. 4 shows the distribution of the number of recognized peaks in 300 C-K X-ray events. The cosmic background and single electron noise were not rejected. The distribution is peaked around $\bar{N}=7.3$ and has a FWHM of 45%. This preliminary result is very encouraging since it represents an energy resolution close to that of a GSC. It should be pointed out that we do not know the Fano factor for the C_2H_5/Ar mixture. We are in the process of searching for more appropriate gas mixtures in order to improve the performance of the detector.

In order to gain more understanding of the process and to be able to optimize the detector parameters we developed a Monte-Carlo computer simulation software. An ex-

ample is given in fig. 5: Based on a given X-ray photon energy, mean ionization energy and Fano factor, we generate an "input distribution" of primary charges (Fig. 5a). Using a random choice process we define the number of injected primary charges for each event. We use known diffusion, drift length, single electron avalanche size distribution and signal rise/fall times to generate the "detected pulse trails" (Fig. 5b). We analyze each event with the correlation method^{19,20} (Fig. 5c) and generate the "measured" distribution of counted primary electrons (Fig. 5d). By means of this computer simulation we can learn about the sensitivity of our method to the different parameters. In particular we can relate the measured distribution width to the input distribution width (i.e. the Fano factor), and use the method as a tool to study the Fano factor of complex gas mixtures for which theoretical calculations are extremely complicated.

Rough localization of the X-ray photons may be obtained with the present detector by reading out electric or optical signals induced during the amplification process at the second multiplication stage. Since the detected charge contains N_e clusters extending typically over 15-20 mm (FWHM), a localization accuracy of the order of $20/\sqrt{N_e}$ mm is expected, i.e. about 7 mm (FWHM) for 279 eV photons, and of about 4 mm (FWHM) for 1 keV photons.

3. Three-dimensional Imaging and Spectroscopy of Mid-energy X-rays with a GSC and Wire-Chamber Readout

Gas Scintillator Counters (GSC) are frequently used for spectroscopy and imaging of soft and medium energy X-rays in many fields such as astronomy, atomic physics, nuclear medicine and material science. These detectors have excellent energy resolution and, as recently demonstrated, have fast timing properties based on the recording of primary scintillation light²¹. This enables them to be used in coincidence experiments with an

efficient background suppression achieved by pulse-shape analysis²¹⁾. The most common method of reading out the light from the GSCs is with photo-multipliers. The localization of X-rays can be done with an array of photomultipliers connected to position-decoding electronics. Such systems are usually expensive, require a complicated gain calibration procedure, suffer from limited stability during operation and from sensitivity to magnetic fields. Alternative methods for GSC readout are continuously being searched for, and ideas like photocathodes coupled to MCPs²²⁾, optical fibers with wave length shifters²³⁾ and wire chambers with TEA or TMAE gaseous photocathodes²⁴⁾ were proposed and tested. We describe here another method, based on a solid-photocathode coupled to an avalanche chamber²⁵⁻²⁷⁾. Such a device efficiently detects Xe scintillation light and provides the energy, localization and timing of X-ray quanta over a large surface. It is based on the conversion of the UV photon on a solid CsI photocathode, and of amplifying the photoelectrons in a LPMSC^{28,29)}.

In Fig. 6 the Solid Photocathode Avalanche Chamber (SPAC) coupled to a GSC through a CaF_2 window is shown. The GSC was designed for X-ray detection in the energy range of 15-150 keV. The system offers the possibility of identifying X-ray interactions, in a high Gamma background, by means of K-fluorescence gating³⁰⁾, pulse-shape analysis and a three-dimensional imaging capability³¹⁾. The GSC is filled with continuously purified Xe at pressures up to 10 bar. X-ray photons enter the detector through a 0.2 mm thick aluminum window, 50 mm in diameter, and interact in a 60 mm deep conversion-drift gap. Primary scintillation is produced at the interaction point. To increase the detection efficiency of primary scintillation light, the inside of the cell is coated with UV-reflective paint. The primary electron cloud drifts in a parallel field towards a 3 mm wide secondary scintillation gap. An electric field of ~ 14 kV/cm across the sec-

ondary scintillation gap yields about 500 photons per initial electron at a pressure of 4.5 bar. The scintillation UV photons ($\lambda=150-190$ nm) interact with the CsI photocathode of the SPAC. Photoelectrons released from the photocathode are immediately multiplied in the parallel plate preamplification gap, and then transferred, amplified and localized in the multiwire amplification stage. The localization of the avalanche is made by charge division, using cathode-induced signals. Anode signals are used for timing, pulse shape analysis and energy measurement. The SPAC is typically operated at 5–20 Torr of CH_4 , which has low self-absorption of UV light. The multistep amplification mode provides high gain, essential for efficient simultaneous detection of primary and secondary scintillation light. The primary scintillation light is detected with 65% efficiency for 60 keV X-ray photons. More details on the detector structure, operation and readout electronics, are given elsewhere²⁹⁾.

3.1 Performance of the GSC with SPAC readout

Energy resolution

In Fig. 7 we present an energy spectrum of an ^{241}Am source obtained with the GSC+SPAC detector. As was discussed above the energy resolution of this device is dominated by several factors: the statistics of the primary electrons in the Xe gas, characterized by the Fano factor, the UV-light collection and conversion efficiency and the statistical fluctuations of the photoelectron amplification process. In the case of 60 keV X-rays detected in our GSC-SPAC detector the contributions due to Fano statistics and to the light collection and amplification in the SPAC are 1.8% and 3.1% FWHM, respectively. The measured value of 4.1% (FWHM) at 60 keV is in good agreement with a total expected resolution of 3.7% (for more details see ref. 29).

Position resolution

The three dimensional conversion point of the X-ray photon is derived from the center of the avalanche in the SPAC plane and the time elapsed between the primary and secondary scintillation pulses. The accuracy of localization is limited by the finite range of the photo-electron, which depends on the Xe pressure, by the distribution of UV-photons detected at the photocathode and by the statistical fluctuations of the amplification process in the SPAC. In our geometry and with a CsI photocathode, about 11000 (± 2000) secondary photoelectrons are associated with a single 60 keV X-ray photon. They are spread over a surface with a distribution having $\sigma = 25$ mm²⁹. This is estimated to contribute about 0.3 mm FWHM to the position resolution. The finite range of photoelectron for 60 keV photon in 4.5 Bar of Xe contributes about 1 mm FWHM, adding up to a total of 1.3 mm FWHM. The measured resolution with a collimated ²⁴¹Am source is shown in Fig. 3 and has 1.8 mm FWHM, after correction for beam divergence due to the slit opening. Obviously more factors like electronic readout noise and inhomogeneity of the photocathode are significant and should be taken into account. The resolution in the third dimension is also a result of several factors - the finite size of the primary ionization cloud, the diffusion along the drift over 6 cm and the finite width of the secondary scintillation light pulse caused by the diffusion and by the size of the scintillation gap itself. In the present detector the resolution in this dimension is about 3 mm FWHM.

Time resolution

The timing properties of the SPAC were studied with triggerable UV light sources of two types: a discharge H₂ lamp and a BaF₂ scintillator coupled to a ²²Na source. The H₂ lamp can yield a high UV-photon flux in each discharge pulse. The time response of the SPAC to a multiple-photon light pulse ($\gg 100$ photons) is shown in Fig. 9; the resolution

is ~ 350 ps (FWHM). The time response of the SPAC to a pulse of ~ 8 photoelectrons (collimated H_2 lamp), which is the typical size of a primary scintillation pulse for 60 keV X-ray in our GSC-SPAC detector (the ratio of secondary-to-primary light is of $\sim 10^3$), is shown in Fig. 10. The resolution is 650 ps FWHM. The time response of the SPAC was measured with a ^{22}Na source and two BaF_2 crystals in a back-to-back geometry. One crystal was mounted on the SPAC and the other was read by a Philips P2020Q photomultiplier (PM), providing a time zero signal. In this configuration mostly single photoelectrons are associated with each trigger of the PM. The time resolution measured in this configuration is 4.5 ns (FWHM) with 10 Torr CH_4 and 4.2 ns (FWHM) with 38 Torr C_2H_6 , for single UV photons.

3.2 Quantum efficiency of the CsI photocathode

The quantum efficiency of the SPAC to Xe (179 nm) and Kr (150 nm) UV radiation was measured with a spherical anode gas scintillation source, described in Ref. 28. The absolute QE of the CsI photocathode was calculated by calibrating the source photon flux, using two different methods: a) the SPAC was replaced by a Hamamatsu PM type R1460, having a LiF window and CsSb-PC. The producer supplies absolute gain curves and QE data over the range of 120–300 nm. b) A small ionization cell filled with TMAE vapor at controlled temperature was mounted directly on the source. The UV light photoionizes the TMAE in the volume between the cathode meshes of the TMAE cell (17.6 mm wide) and induces measurable photo-current on the anode wires and cathodes. The source intensity was derived from the known photon mean free path⁵⁾ and the QE³¹⁾ of TMAE. A reference photomultiplier continuously monitored the source relative intensity. More details of these measurements will be given in ref. 32.

The CsI layer was prepared by vacuum evaporation onto a polished metallic surface,

cleaned by glow discharge prior to evaporation. The photocathodes were installed in the detector immediately after evaporation. Their contact with air was between 1-2 min, which supposedly has only a minor effect on the QE³³⁾. The detector was either immediately evacuated to a vacuum of the order of 10^{-2} Torr, or flushed with CH₄ during hours or days, prior to operation. There was no noticeable change in the QE during the pumping or flushing process, as opposed to the observation of the authors of ref. 33. Several photocathode substrates were tested: copper, stainless steel, aluminized copper and aluminized stainless steel. The QE was found to be insensitive to the substrate material, although the aging of the photocathode was dependent on the quality and type of the surface³²⁾. The following values of the absolute quantum efficiency (QE) were measured with a SPAC, operating at 20 Torr CH₄ and with a 1500 nm thick CsI photocathode:

$$\text{Xe light } (\bar{\lambda} = 170 \text{ nm}): \text{ QE} = 10\% \pm 2\%$$

$$\text{Kr light } (\bar{\lambda} = 150 \text{ nm}): \text{ QE} = 20\% \pm 4\%$$

The dependence of the quantum efficiency of the SPAC on the CH₄ operation pressure is shown in Fig. 11. There is a drop of about 20% in QE for atmospheric pressure relative to 20 Torr of CH₄. Fig. 12 shows the dependence of the QE on photocathode thickness. Only a small variation is noticeable with a peak around 600 nm.

It should be mentioned that our QE values are similar to those given by Hamamatsu³⁴⁾ and by ref. 35. However, much larger QE values were recently reported by the authors of ref. 33. The origin of this discrepancy (a factor of 3-4) has not yet been clarified. Both groups use the same CsI material and employ the same deposition techniques.

An important practical property of the CsI photocathode is its resistance under exposure to humid air and its survival under high doses of UV radiation. In addition, its operation inside a gaseous amplifier raises the question of damage due to the bombard-

ment by hydrocarbon radicals. Fig. 13 shows the decay of the QE due to exposure of the photocathode to air. It is important to note that the decay time constant is of the order of an hour. However, since our mounting procedure involves an exposure to air of about 1-2 min, it may well be that some damage, of unknown extent, has already been initiated. The aging of the CsI photocathode induced by the UV flux and the feedback of positive ions was studied by irradiating the SPAC through its CaF_2 window. Both the Xe UV-light source and a low-pressure Hg/Ar lamp (ORIEL) were used. The Hg/Ar lamp can provide extremely high photon flux, of more than 10^{13} photons/ $\text{mm}^2 \cdot \text{s}$. The SPAC was operated in different modes in order to control the flow of positive ions back-streaming onto the photocathode. Some examples are given here and more details can be found in references 29 and 32. Fig. 14 shows the decay of the QE under an illumination of 10^8 photons/ $\text{mm}^2 \cdot \text{s}$. The total detector gain in the two curves is constant but is differently distributed between the two amplification stages. As expected, a higher gain in the preamplification stage induces a faster decay of the photocathode, due to the positive ions feedback. In fig. 15 curves a) and b) demonstrate the effect of the gas pressure: for the same total gain a slower decay occurs at higher pressure. This is interpreted to be due to the lower velocity of molecular radicals in the gas. Comparing b) and c) in the same figure we see that an increase by a factor of 100 in photon flux causes more damage than an equal increase in gain of the preamplification stage. From the QE decay data at different operation conditions we can extract a typical "life-time" for the photocathode. For example, at 20 Torr CH_4 , with a gain of 100 in the preamplification stage (Fig. 15b), the photocathode decays to 50% of its initial value after a total charge, measured at the second stage, of 0.6 mC, equivalent to a dose of 10^{13} incident photons/ mm^2 . In our GSC-SPAC detector each 60 keV X-ray photon induces about 10 photons/ mm^2 . Therefore an effective life-time of the photocathode is associated with a dose of about 10^{12} X-rays under these operative conditions.

We carried out a SEM (Scanning Electron Microscope) study of the irradiated photocathodes, in an attempt to observe structural and, using the secondary X-ray emission, chemical changes involved in the various aging processes. There were no significant chemical changes observed in any of the samples. The photocathodes which were exposed to air showed a change in structure, in the form of crystallization, developed mainly along defects in the metallic backing. A shadowing effect with the topology of the preamplification anode wires was observed on the photocathode which was operated at high gain in the first preamplification stage. Further aging studies are in progress.

4. A Fast Imaging Device for Soft-to-hard X-rays.

The last application presented here is a fast X-ray imaging detector based on a solid foil converter coupled to a LPMSO. This device may be used over a broad range of X-ray energies by a proper choice of the photocathode material and thickness. Many applications can be envisioned such as X-ray microscopy, surface analysis with electron microbeams, X-ray diffraction in protein crystallography using intense Synchrotron Radiation Sources, industrial radiography for safety and quality controls, study of time-resolved phenomena such as proteins in muscles or plasma diagnostics involved in thermo-nuclear fusion and X-ray detection in Transition Radiation detectors.

The obvious advantages of a solid photocathode, as compared to gaseous conversion, are the production of parallax-free images and a fast response. The low-pressure operation mode of the electron multiplier enables a high rate capability due to the low-charge density in the avalanche and fast ions removal.

A study of X-ray induced electron emission from various metallic and insulator materials³⁶⁾, indicates the advantages of materials like CsI and CuI which have a very high yield of secondary electrons in the energy range below 5 eV. The yield of secondary

emission was found to be directly proportional to the absorption cross section. In particular for X-ray photons of energy between 0.6–2 keV more than one secondary electron is emitted per incident photon from a 1000 Å thick CsI layer in a transmission geometry. Based on these encouraging data we decided to couple a thin transmission CsI photocathode to a low-pressure electron multiplier. Fig. 16 shows the structure of the detector. It consists of several, 80 mm diameter, mesh electrodes mounted in a vacuum vessel. All the mesh frames and spacers are made of G-10 epoxy resin. A thin window, made of 100 μm Kapton was used. The photocathode is made of a thin layer (400–2000 Å) of CsI, vacuum deposited on commercial 1.5 μm thick aluminized mylar. The metallic substrate is important for providing the potential to this electrode. The electrons emitted from the photocathode are immediately amplified in a 3 mm wide parallel gap, transferred and further amplified in a second parallel gap structure. A different configuration, in which the electrons emitted from the photocathode are first collected in a 3 mm drift region and only then transferred and amplified, was also tested.

The detector was operated with 10–40 Torr of C_2H_6 or dimethylether (DME). Both gases provide high gain, up to 10^7 for single electrons, in a single parallel gap and in a double step amplification structure. However, DME provides a more stable operation with fewer secondary avalanches. Fig. 17 shows the amplification curve of a single gap with DME at 20 Torr when operated with UV photons. The detector was tested with 6 keV X-rays from ^{55}Fe source. Fig. 18 shows the pulseheight spectrum obtained from the photocathode with and without the CsI layer. An electron yield due to the Al layer is evident in a), and an enhancement of the yield due to the CsI layer is shown in b). Under the same conditions a spectrum induced by UV photons is given in c). The photocathode obviously yields several electrons for each absorbed X-ray photon.

The current from the last anode of the detector is shown in Fig. 19 as function of the voltage on this anode; a plateau extends over a few hundred volts. The plateau region was used for the measurement of the QE of the CsI in our gaseous electron multiplier. For this purpose we calibrated our X-ray source with a SiLi detector of known geometry. The CsI layer of 480 Å yielded a QE of 0.92%, for 90° incidence angle of an X-ray beam. The absorption fraction of X-rays in this CsI layer is 1%. This demonstrates the high efficiency of the device for detecting the secondary electrons. In order to increase the detection efficiency a thicker CsI layer has to be used. A promising possibility is the use of a grazing incidence angle geometry (Fig. 20) which provides a larger absorption length for X-rays without increasing the actual thickness which may reduce electron extraction³⁷).

In the future we will study the QE of this photocathode, as well as other materials, under angular incidence, over a broad energy range. We will study the photocathode stability under high flux radiation and will proceed with imaging and timing studies.

5. Summary

In this article we have discussed various applications of the low pressure multistep gaseous electron multiplier, in the field of X-ray spectroscopy and imaging.

First attempts to resolve ultrasoft X-rays by counting single electrons deposited in low-pressure gas yielded very satisfactory results. The energy resolution is close to that of GSC's and should be improved, according to our Monte-Carlo simulations, by the use of Penning mixtures with low Fano-factors.

A large-surface imaging UV-photon detector, combining a CsI photocathode and a wire chamber, provides an efficient readout for GSC's, with fast timing and good localization properties for mid-energy X-rays. The CsI photocathode has a quantum efficiency of 10% at 170 nm. Its stability was systematically investigated.

The possibility to increase the QE of CsI photocathodes with adsorbed TMAE, reported recently by the authors of ref. 33, will be tested with the GSC-SPAC, in an attempt to further improve energy and time resolution. It is an interesting development since it also seems to improve the stability of the photocathode in exposure to air. An enhanced photocathode life-time is expected if it is decoupled from the amplification stage by a low-field collection gap, and if the amplification is distributed among a multiplicity of successive elements, so as to reduce positive ion feedback²⁶⁾. A quantitative study is needed to find a compromise with the timing properties of such a device.

Our fast gaseous UV-imaging photomultiplier may be an ideal tool for the readout of solid scintillators (BaF_2 , KMgF_2 ³⁸⁾ and others) in particle physics, medical or industrial positron tomography and gamma radiography. Single photon impact can be localized with an accuracy of 0.2 mm (FWHM)²⁵⁾. Other possible applications are UV-astronomy, plasma diagnostics and Čerenkov ring imaging. Different photocathodes, also for the visible spectrum, will be investigated for this purpose.

A fast high rate imaging X-ray detector, based on a conversion foil coupled to a multi-step avalanche multiplier, is being studied. It should provide a parallax-free high accuracy localization of X-rays over a broad energy range, with subnanosecond time resolution (Sect. 3.1). The stable operation with DME at low-pressures, investigated in this work, ensures a low detector aging. The efficient secondary-electron detection provides high counting efficiencies for X-ray quanta converted in the photocathode foils. Systems combining several layers of detectors based on this principle are suited for applications in medical and industrial radiography and for high rate X-ray diffraction experiments at Synchrotron Radiation Accelerators. Such detectors enable the study of fast dynamical processes.

We would like to thank Mrs. Y. Gil, Mr. J. Asher, Mr. M. Klin and Mr. L. Sapir for their valuable technical assistance. This work was partially supported by the Minerva foundation, Munich, Germany.

Claims

1. An X-ray detector comprising:
 - a photocathode arranged to receive X-ray radiation and being operative to provide in response

thereto an output of electrons; and

at least one electron multiplier operative at subatmospheric pressure and in response to the output of electrons from the photocathode to provide an avalanche comprising an increased number of electrons.

5

2. An X-ray detector comprising:

a photocathode arranged to receive X-ray radiation and being operative to provide in response thereto an output of electrons; and

10

at least one multi-stage electron multiplier operative in response to the output of electrons from the photocathode to provide an avalanche comprising an increased number of electrons.

3. An X-ray detector according to claim 1 or 2 and also comprising at least one detecting means for detecting an indication of at least one characteristic of the electron avalanche produced by the electron multiplier.

15

4. An X-ray detector according to claim 1 or 2 and wherein the at least one electron multiplier comprises at least one detecting means for detecting an indication of at least one characteristic of the electron avalanche produced by the electron multiplier.

20

5. An X-ray detector according to claim 3 or claim 4 and wherein said detecting means comprises photon detection means for detecting photons emitted during the electron avalanche.

25

6. An X-ray detector according to any of the preceding claims and wherein said detecting means comprises electron detection means for detecting the electrons produced by the electron avalanche, the electron detection means comprising a plurality of pad electrode assemblies for collecting the electrons produced by the electron multiplier.

30

7. An X-ray detector according to any of the preceding claims wherein the photocathode is generally planar and is configured and arranged to receive X-ray radiation impinging on both sides thereof.

35

8. An X-ray detector assembly comprising:

a gas filled enclosure; and

a plurality of X-ray detectors located interiorly of the gas filled enclosure, each individual one of the plurality of X-ray detectors being according to any of the preceding claims 1-7.

40

9. An X-ray detecting method comprising the steps of:

providing a photocathode arranged to receive X-ray radiation and being operative to provide in response thereto an output of electrons; and

45

in response to the output of electrons from the photocathode, providing at sub-atmospheric pressure an avalanche comprising an increased number of electrons.

10. An X-ray medical diagnostic method comprising the steps of:

radiating a subject to be diagnosed with X-ray radiation; and

50

employing an X-ray detector according to any of claims 1 - 8 in order to perform radiography by detecting said X-ray radiation.
